IMPORTANCE Type 2 diabetes (T2D) is the leading cause of kidney disease in the US. It is not known whether glucose-lowering medications differentially affect kidney function.

OBJECTIVE To evaluate kidney outcomes in the Glycemia Reduction Approaches in Diabetes: A Comparative Effectiveness (GRADE) trial comparing 4 classes of glucose-lowering medications added to metformin for glycemic management in individuals with T2D.

DESIGN, SETTING, AND PARTICIPANTS A randomized clinical trial was conducted at 36 sites across the US. Participants included adults with T2D for less than 10 years, a hemoglobin A_{1c} level between 6.8% and 8.5%, and estimated glomerular filtration rate (eGFR) greater than or equal to 60 mL/min/1.73 m² who were receiving metformin treatment. A total of 5047 participants were enrolled between July 8, 2013, and August 11, 2017, and followed up for a mean of 5.0 years (range, 0-7.6 years). Data were analyzed from February 21, 2022, to March 27, 2023.

INTERVENTIONS Addition of insulin glargine, glimepiride, liraglutide, or sitagliptin to metformin, with the medication combination continued until the HbA_{1c} was greater than 7.5%; thereafter, insulin was added to maintain glycemic control.

MAIN OUTCOMES AND MEASURES Chronic eGFR slope (change in eGFR between year 1 and trial end) and a composite kidney disease progression outcome (albuminuria, dialysis, transplant, or death due to kidney disease). Secondary outcomes included incident eGFR less than 60 mL/min/1.73 m², 40% decrease in eGFR to less than 60 mL/min/1.73 m², doubling of urine albumin-to-creatinine ratio (UACR) to 30 mg/g or greater, and progression of Kidney Disease Improving Global Outcomes stage. Analyses were intention-to-treat.

RESULTS Of the 5047 participants, 3210 (63.6%) were men. Baseline characteristics were mean (SD) age 57.2 (10.0) years; HbA_{1c} 7.5% (0.5%); diabetes duration, 4.2 (2.7) years; body mass index, 34.3 (6.8); blood pressure 128.3/77.3 (14.7/9.9) mm Hg; eGFR 94.9 (16.8) mL/min/1.73 m²; and median UACR, 6.4 (IQR 3.1-16.9) mg/g; 2933 (58.1%) were treated with renin-angiotensin-aldosterone inhibitors. Mean chronic eGFR slope was –2.03 (95% CI, –2.20 to –1.86) mL/min/1.73 m² per year for patients receiving sitagliptin; glimepiride, –1.92 (95% CI, –2.08 to –1.75) mL/min/1.73 m² per year; liraglutide, –2.08 (95% CI, –2.26 to –1.90) mL/min/1.73 m² per year; and insulin glargine, –2.02 (95% CI, –2.19 to –1.84) mL/min/1.73 m² per year (*P* = .61). Mean composite kidney disease progression occurred in 135 (10.6%) patients receiving sitagliptin; glimepiride, 155 (12.4%); liraglutide, 152 (12.0%); and insulin glargine, 150 (11.9%) (*P* = .56). Most of the composite outcome was attributable to albuminuria progression (98.4%). There were no adverse kidney events attributable to medication assignment.

CONCLUSIONS AND RELEVANCE In this randomized clinical trial, among people with T2D and predominantly free of kidney disease at baseline, no significant differences in kidney outcomes were observed during 5 years of follow-up when a dipeptidyl peptidase 4 inhibitor, sulfonylurea, glucagonlike peptide 1 receptor agonist, or basal insulin was added to metformin for glycemic control.

Wexler, MD, MSc, c/o The George Washington University Biostatistics Center/GRADE Coordinating Center, G110 Executive Blvd, Ste 750, Rockville, MD 20852 (grademail@ bsc.gwu.edu). iabetes is the leading cause of chronic kidney disease and kidney failure in the US and most of the world. Achieving and maintaining glycemic control is critical for preventing or delaying the development of diabetic kidney disease (DKD).¹ Clinical trials in patients with type 1 diabetes and type 2 diabetes (T2D) have consistently demonstrated that intensive glycemic control reduces the risk of developing albuminuria,²⁻⁴ and long-term follow-up of some cohorts suggests that intensive glycemic control also prevents a decrease in estimated glomerular filtration rate (eGFR) and kidney failure.^{5,6}

More recently, in T2D, several classes of glucose-lowering drugs have been demonstrated to have kidney benefits that appear independent of glycemic effects, an effect mostly seen in studies of people with DKD, atherosclerotic cardiovascular disease, or high atherosclerotic cardiovascular disease risk. Dipeptidyl peptidase 4 (DPP-4) inhibitors, glucagonlike peptide-1 (GLP-1) receptor agonists, and sodium-glucose cotransporter-2 (SGLT2) inhibitors have all been shown to reduce albuminuria in DKD, compared with placebo or other glucose-lowering drugs.7-12 In addition, SGLT2 inhibitors have been clearly demonstrated to slow the decrease in eGFR over time, 10,11,13 and GLP-1 receptor agonists have shown potential benefits with regard to eGFR loss in short-term studies and secondary analyses of cardiovascular outcome trials.^{9,12} Whether people at an earlier stage of diabetes, largely free of DKD, derive differential benefit from treatment with non-SGLT2 inhibitor glucose-lowering medication classes is unknown.

The Glycemia Reduction Approaches in Diabetes: A Comparative Effectiveness (GRADE) Study aimed to compare glycemic and other outcomes among 4 commonly used classes of glucose-lowering medications added to metformin. The medications, selected to represent the most popular classes available at the time of study design and launch in 2013, were the DPP-4 inhibitor sitagliptin, the sulfonylurea glimepiride, the GLP-1 receptor agonist liraglutide, and the basal insulin glargine.^{14,15} As noted, DPP-4 inhibitors and GLP-1 receptor agonists have shown modest kidney benefits, chiefly albuminuria lowering, in placebo-controlled trials. In contrast to recent cardiovascular outcome trials, GRADE enrolled a diverse US cohort with shorter duration of diabetes, predominantly without cardiovascular and kidney complications at baseline, and maintained overall good glycemic management across all 4 treatment groups. GRADE reported modest differences in time to glycemic progression¹⁶ and no significant differences in overall microvascular outcomes in GRADE.¹⁷ In this report, we evaluate the effects of the GRADE interventions on detailed kidney outcomes.

Methods

Main Outcomes and Measures

GRADE and its major outcomes have been previously described.¹⁴⁻¹⁷ The GRADE protocol is given in Supplement 1, and the inclusion and exclusion criteria are presented in the eMethods 1 in Supplement 2. The trial was approved by the institutional review boards of the George Washington

Key Points

Question Do glucose-lowering medications have different effects on kidney outcomes?

Findings In this randomized clinical trial including 5047 patients with type 2 diabetes, those receiving metformin treatment and predominantly without kidney disease at baseline were randomly assigned to treatment with a sulfonylurea, a dipeptidyl peptidase 4 inhibitor, a glucagonlike peptide 1 receptor agonist, or basal insulin; all groups had good glycemic and blood pressure management. There were no significant differences in decreased estimated glomerular filtration rate, progression of albuminuria, dialysis, kidney transplant, or death during 5 years of follow-up.

Meaning In patients with type 2 diabetes treated with metformin, kidney outcomes do not appear to differ by treatment with 1 of 4 second glucose-lowering medication classes evaluated in this randomized clinical trial.

University and all clinical centers. All participants provided written informed consent and received financial compensation. This study followed the Consolidated Standards of Reporting Trials (CONSORT) reporting guideline.

Trial Design

GRADE was a parallel-group comparative effectiveness clinical trial conducted in 36 clinical centers across the US. Randomization was performed via a central web-based system and stratified by site. Treatment assignment was unmasked to the participants and clinic staff; laboratories, reading centers, and event adjudicators were masked to treatment assignment.

Participants

Participants had T2D diagnosed at age 30 years or older (≥20 years in self-reported American Indian or Alaska Native individuals), diabetes duration less than 10 years, treated with metformin 1000 to 2000 mg/d, with hemoglobin A_{1c} (Hb A_{1c}) 6.8% to 8.5% (to convert to proportion of total hemoglobin, multiply by 0.01) at randomization. Potential participants with a history of a major cardiovascular event within the previous year and New York Heart Association Class II to IV heart failure were excluded. At the outset of the trial, men with a creatinine level greater than 1.5 mg/dL (to convert to micromoles per liter, multiply by 88.4) and women with a creatinine level greater than 1.4 mg/dL were excluded; this threshold was subsequently replaced by estimated glomerular filtration rate (eGFR) less than 30 mL/min/1.73 m² to be consistent with changes in practice and metformin prescribing (protocol version 1.6, August 2016). Participants were recruited between July 8, 2013, and August 11, 2017, and followed up for a mean duration of 5.0 (range, 0-7.6) years through April 30, 2021, with 85.3% completing at least 4 years of follow-up.^{16,17}

Interventions

Participants were randomly assigned to start sitagliptin, glimepiride, liraglutide, or insulin glargine, 100 U/mL, in addition to metformin. The medication combination was continued until the HbA_{1c} was greater than 7.5% and confirmed; thereafter, basal and prandial insulin, if needed, were added

to maintain glycemic control. All medications were dosed according to their labeling guidelines. Starting in 2018, updated consensus recommendations on the choice of glucoselowering medications (including GLP-1 receptor agonists and SGLT2 inhibitors) in the setting of prevalent cardiovascular and, later, kidney disease were issued by the American Diabetes Association/European Association for the Study of Diabetes.^{18,19} These recommendations were shared with participants eligible for these interventions and their health care professionals. Usual care clinicians managed all medication therapy other than the protocol-assigned glucose-lowering medications, including SGLT2 inhibitors or nonstudy GLP-1 receptor agonists.

Outcomes and Assessments

Participants had in-person study visits every 3 months. Weight and seated standardized blood pressure (mean of 3 measurements using a calibrated sphygmomanometer) were measured per study protocol. Kidney function and damage were assessed by assays of creatinine and albumin.²⁰ Serum creatinine was determined annually, and a spot urinary albuminto-creatinine ratio (UACR) was determined every 6 months. Creatinine levels were measured in serum and urine by an enzymatic method (creatinase) (Roche cobas 6000 system; Roche Diagnostics) with trueness verified using National Institute of Standards and Technology standard materials.²¹ The eGFR was calculated from the measured creatinine level using the Chronic Kidney Disease Epidemiology Collaboration equation, including self-reported race and ethnicity as a variable to maintain consistency with previously reported results.^{14,22} Urine albumin levels were measured using an immunoturbidimetric method (Roche) standardized against a reference preparation. Moderately increased albuminuria was defined as greater than or equal to 30 to less than 300 mg/g of creatinine, confirmed at a subsequent visit, and severely increased albuminuria as greater than or equal to 300 mg/g of creatinine. We also report the prevalence and treatment of hypertension over follow-up and off-protocol use of SGLT2 inhibitors and GLP-1 receptor agonists. Cause of death was adjudicated by an outcomes committee blinded to treatment assignment.

The statistical analysis plan (Supplement 1) for this report was prepared after the primary outcomes of GRADE, including the null result for the primary microvascular outcomes, were known. Therefore, the statistical analysis plan for this report prespecified outcomes that were designed to maximize sensitivity to detect a difference among treatment groups (or convincingly demonstrate a null result) in a cohort with high eGFRs and low rates of albuminuria (and therefore low risk for advanced kidney disease outcomes). We specified the 2 coprimary outcomes. The first of these was the slope of (change in) eGFR between year 1 and the end of follow-up, termed chronic eGFR slope, a valid surrogate for kidney disease progression in low-risk populations.²³ Since creatinine levels were measured annually, the year 1 measurement was selected as the starting point to assess slope to exclude the effect of shortterm, hemodynamic effects of study medications or resolution of hyperglycemia at study entry with consequent reduction of hyperfiltration on eGFR. The second outcome was a composite kidney disease progression outcome, defined as an increase over time in albuminuria stage according to the Kidney Disease Improving Global Outcomes (KDIGO) categories (eg, for participants with UACR<30 mg/g [KDIGO A1] at baseline, confirmed progression to UACR≥30 mg/g [KDIGO A2], and for those with UACR 30-299 mg/g, progression to UACR≥300 mg/g [KDIGO A3]), kidney transplant, dialysis, or death from kidney disease. This outcome was designed primarily to reflect albuminuria progression as an early marker of kidney disease progression, with kidney-associated severe outcomes included to capture competing risks that would prevent assessment of albuminuria.

Secondary outcomes were also selected to maximize sensitivity: change in eGFR from baseline to year 1 (1-year eGFR slope) and from baseline to end of study (total eGFR slope), time to progression of eGFR to less than 60 mL/min/1.73 m² among those with baseline eGFR above that threshold, time to a 40% decrease in eGFR to less than 60 mL/min/1.73 m², time to doubling of the UACR to a level greater than or equal to creatinine 30 mg/g, and time to KDIGO category increase from baseline (ie, moving to a higher eGFR [G1 through G5] or albuminuria category [A1 through A3]).²⁴

Statistical Analysis

Data analysis was performed from February 21, 2022, to March 27, 2023. Continuous variables were modeled over the entire duration of follow-up. Categorical variables and cumulative incidence rates are reported at 4 years of follow-up, when 85.3% of the participants remained in the study. The statistical analysis plan prespecified evaluation of the following subgroups: age (<45, 45-59, ≥60 years), sex (male, female), self-reported race (Black, White, other) and ethnicity (Hispanic, non-Hispanic), HbA_{1c} level (tertiles), body mass index (BMI) (tertiles), duration of diabetes (tertiles), baseline hypertension (defined as measured blood pressure \geq 130/80 mm Hg or treatment with blood-pressure-lowering medication, including reninangiotensin-aldosterone system [RAAS] inhibitors), and eGFR less than 60 mL/min/1.73 m² vs 60 mL/min/1.73 m² or higher. GRADE recruited a diverse cohort representative of people affected by T2D. Since kidney outcomes differ by race and ethnicity, we evaluated whether there were differences in outcomes by race and ethnicity in GRADE.

Analyses were intention-to-treat and were restricted to participants with at least 1 postbaseline visit (**Figure 1**). The eGFR slope models use generalized estimating equation models with annual eGFR starting from year 1 as the response and the following covariates: baseline eGFR, time from baseline in whole years, GRADE treatment group, and time-by-treatment interaction.^{25,26} The test of the interaction term in this model tests for heterogeneity of slopes. We plotted eGFR over time showing means (SDs). Sensitivity analyses refit the generalized estimating equation model starting from baseline instead of year 1 and removing the adjustment for baseline eGFR.

Evaluation of kidney disease progression over the duration of follow-up is depicted using Kaplan-Meier plots by treatment group and using the log-rank test to assess treatment differences with treatment group as the only covariate. For each secondary outcome, we tested for treatment heterogeneity

Assignment to the 4 treatment groups, numbers of drop-in/drop-out, and numbers included in intention-to-treat (ITT) and per-protocol analyses. For the ITT analyses, 98 participants in the glargine (n = 36), glimepiride (n = 22), liraglutide (n = 28), and sitagliptin (n = 12) groups were removed from the randomized group (n = 5047) due to not having at least 1 follow-up estimated glomerular filtration rate or 1 follow-up urinary albumin-to-creatinine ratio measure obtained after the baseline visit. For the per-protocol analyses, 247 participants in the glargine (n = 61), glimepiride (n = 44), liraglutide (n = 112), and sitagliptin (n = 30) groups were removed from the randomized group (n = 5047) if they did not attend any follow-up visits or did not take at least 1 dose of their randomized medication. GLP-1 RA indicates glucagonlike peptide-1 receptor agonist; SGLT2, sodium-glucose cotransporter-2.

using similar models and multiple comparison adjustment. Tests of treatment heterogeneity for the 2 primary outcomes across the prespecified subgroups were carried out by adding treatment by subgroup interaction terms to the models described above. The *P* values from the interaction terms for these models were adjusted for false discovery using the Benjamini-Hochberg procedure (details in eMethods 2 in Supplement 2). For the specified coprimary outcome of composite kidney disease progression, the number of events that occurred in the study allowed a detection of hazard ratios (HRs) of 1.30 assuming 70% power, 1.33 assuming 80% power, and 1.38 assuming 90% power between any 2 treatment groups (for a total of 6 pairwise treatment group comparisons).²⁷

We conducted 2 sets of sensitivity analyses. Per-protocol sensitivity analyses were censored at the last visit before deviation from the assigned treatment regimen. The second set of sensitivity analyses explored the effect of SGLT2 inhibitors and GLP-1 receptor agonists not in the protocol (ie, prescribed by the participants' personal clinicians) on the primary outcomes. Specific methods are described in eMethods 2 in Supplement 2).

All analyses were conducted with R, version 4.0.3 (R Foundation for Statistical Computing, 2022). All tests were unpaired and 2-sided, with statistical significance set at P < .05.

Results

Baseline Characteristics

Baseline characteristics of the 5047 participants (3210 men [63.6%], 1837 women [36.4%]) are presented in **Table 1**. Mean (SD) age was 57.2 (10.0) years; BMI, 34.3 (6.8) (calculated as

weight in kilograms divided by height in meters squared); and blood pressure, 128.3/77.3 (14.7/9.9) mm Hg. A total of 2933 (58.1%) patients were treated with RAAS inhibitors at baseline. Mean (SD) baseline eGFR was 94.9 (16.8) mL/min/1.73 m², and 125 (2.5%) participants had an eGFR less than 60 mL/min/ 1.73 m². The UACR was moderately elevated in 716 (14.2%) individuals and severely elevated in 84 (1.7%); median UACR was 6.4 (IQR, 3.1-16.9). The mean (SD) duration of the diagnosis of diabetes was 4.2 (2.7) years.

Follow-up

Ninety-eight patients were excluded from the analysis due to missing data (eTable 1 in Supplement 2). Over the course of the trial, participants had mean (SD) HbA_{1c} of 7.2% (1.2%) and blood pressure of 128/76 (16/10) mm Hg, with 2510 (64.4%) treated with RAAS inhibitors and 3201 (82.2%) treated with any blood-pressure-lowering medication at year 4 (eTable 2 in Supplement 2) with minor differences across some treatment groups. Mean (SD) eGFR was measured 5.4 (1.5) times per participant and UACR was measured 9.8 (3.0) times per participant. Rates of permanent discontinuation of assigned study medication were 14% for glargine, 23% for glimepiride, 23% for liraglutide, and 19% for sitagliptin.¹⁶

Kidney Outcomes

The mean eGFR decreased during the trial (**Figure 2**A), with a chronic slope from year 1 to trial end of -2.01 (95% CI, -2.10 to -1.92) mL/min/1.73 m² per year among all study participants. Mean chronic eGFR slope was -2.03 (95% CI, -2.20 to -1.86) mL/min/1.73 m² per year for participants receiving sitagliptin; glimepiride, -1.92 (95% CI, -2.08 to -1.75) mL/min/1.73 m² per year; liraglutide, -2.08 (95% CI, -2.26 to -1.90)

Abbreviations: ACEi, angiotensin converting enzyme inhibitor; ARB, angiotensin receptor blocker; ASCVD, atherosclerotic cardiovascular disease; BMI, body mass index (calculated as weight in kilograms divided by height in meters squared); eGFR, estimated glomerular filtration rate; HbA_{1c}, hemoglobin A_{1c}; MI, myocardial infarction; UACR, albumin-to-creatinine ratio.

SI conversion factor: to convert $\mathsf{HbA}_{\mathsf{1c}}$ to proportion of total hemoglobin, multiply by 0.01.

^a Race and ethnicity were determined by participant self-report.

mL/min/1.73 m² per year; and insulin glargine, -2.02 (95% CI, -2.19 to -1.84) mL/min/1.73 m² per year (P = .61). There were no significant differences in slope among the treatment groups. Similarly, there were no significant differences in mean total slope starting from baseline, change in eGFR during the first year of the study, confirmed progression to eGFR less than 60 mL/min/1.73 m², or confirmed 40% decrease in eGFR (**Table 2, Table 3** and Figure 2A,C,E, and F).

The composite kidney disease progression coprimary outcome occurred among 592 participants (Figure 2D). Most of these events (489 [82.6%]) consisted of progression from normal to moderately elevated albuminuria; 93 patients (15.8%) developed severely elevated albuminuria; and 10 had dialysis, kidney transplant, or death from kidney disease (eFigure 1 and eFigure 2 in Supplement 2). By year 4, the Kaplan-Meier-estimated cumulative incidence of the coprimary outcome of progression of kidney disease was 10.3% in the glargine group, 10.4% in the glimepiride group, 10.1% in the liraglutide group, and 9.3% in the sitagliptin group. There were no significant differences across treatment groups for the

^a Coprimary outcome. Kidney disease progression is progression of albuminuria stage or dialysis, transplant, or kidney death. Other outcomes are prespecified secondary outcomes.

duration of study follow-up (log-rank P = .56) (Table 3, Figure 2D). The 5-year cumulative incidence of the coprimary composite kidney disease progression was 11.7% overall at 5 years. Secondary outcomes (Table 3 and Figure 2E-H) did not differ significantly across treatment groups. There was no significant heterogeneity across subgroups, including age, sex, race and ethnicity, HbA_{1c} tertiles, BMI tertiles,

duration of diabetes tertiles, presence of baseline hypertension, treatment for hypertension or with RAAS inhibitors at baseline, and eGFR less than 60 mL/min/1.73 m² in any of the primary or secondary outcomes (eTable 3 in Supplement 2).

Results of exploratory per-protocol analysis were largely consistent with the main findings (eResults and eTables 4 and 5 in Supplement 2); there were lower HRs for kidney disease progression in the liraglutide and sitagliptin groups than in the intention-to-treat analyses with no significant difference across treatment groups (P = .07 for treatment group differences). Use of SGLT2 inhibitors and off-protocol GLP-1 receptor agonists differed across treatment groups, with only 5.5% of the liraglutide group adding an SGLT2 inhibitor or using a different GLP-1 receptor agonist. In the non-liraglutide treatment groups, between 10.5% and 12.0% used either of these medication classes during the trial, with 4.8% of glargine, 5.8% of glimepiride, and 6.2% of sitagliptin-assigned participants adding an SGLT2 inhibitor (eTable 6 in Supplement 2). Sensitivity analyses showed that there were no statistically significant differences in coprimary outcomes in participants with use of SGLT2 inhibitors or off-protocol GLP-1 receptor agonists (eTable 7 in Supplement 2).

Discussion

In people with T2D treated with metformin and predominantly normal clinical kidney parameters at baseline, there were no significant differences in eGFR slope or albuminuria progression by treatment with 4 common classes of glucose-lowering medication during 5 years of follow-up. We evaluated many participants and a range of complementary early sensitive kidney outcomes, but we did not observe any significant differences by treatment assignment in intention-to-treat analyses. These results suggest that neither DPP-4 inhibitor, GLP-1 receptor agonist, sulfonylurea, nor basal insulin has a substantial comparative advantage when added to metformin for preventing the development or progression of DKD in T2D in the first decade after diagnosis.

The 5-year cumulative incidence of the coprimary composite kidney disease progression outcome, which largely represented albuminuria progression, was 11.7% at 5 years. Given its known morbidity, this represents a clinically meaningful incidence of DKD. However, this percentage is lower than the 5-year incidence observed in the UKPDS cohort of patients with newly diagnosed diabetes, in which 17.3% developed moderately increased albuminuria and 3.1% of participants developed severely elevated albuminuria over the same time frame.²⁸ This may reflect better overall glycemic and blood pressure management and more prevalent use of RAAS inhibitors in GRADE.

The eGFR loss in GRADE was significant, with a mean chronic eGFR slope of -2.01 (95% CI, -2.10 to -1.92) mL/min/ 1.73 m² from a baseline of 94.9 mL/min 1.73m². The observed rate of eGFR decrease is more rapid than the median decrease of approximately -1.0 mL/min/1.73 m² observed in a contemporary, nondiabetic cohort with similar age and eGFR.²⁹ The observed rate of eGFR decrease in GRADE is slower than in the placebo arm of the DECLARE-TIMI 58 study (-2.5 mL/min/1.73 m²), ^{13,30} but greater than that observed in the placebo arm of the EMPA-REG Outcome Study (-1.46 mL/min/1.73 m²).³¹

This rate of eGFR loss and albuminuria progression afforded an opportunity to detect significant differences in outcomes according to treatment assignment, but none were observed. In addition, prespecified subgroup analyses evaluating heterogeneity by age, sex, race and ethnicity, HbA_{1c} level, BMI, duration of diabetes, hypertension, and eGFR were null. Perprotocol sensitivity analyses showed more favorable HRs for sitagliptin and liraglutide with regard to albuminuria-related outcomes. These differences were not statistically significant and should be interpreted with caution, but it is not possible to rule out that benefits might emerge with additional follow-up time. Kidney benefits may take longer to become apparent earlier in the course of T2D, as has been observed in type 1 diabetes, where differences in kidney parameters emerge after 10 years of intensive glycemic management.^{6,32}

Our null results may appear to contrast with findings from randomized clinical cardiovascular outcome trials involving incretin-based therapies, some of which showed improved kidney outcomes.¹¹⁻¹⁵ For example, in clinical trials, the GLP-1 receptor agonists liraglutide (LEADER trial⁸) and dulaglutide (REWIND trial³³) were associated with a reduced risk of a composite kidney outcome, largely due to reduced progression to severely elevated albuminuria and slower eGFR loss in post hoc analyses. A meta-analysis of GLP-1 receptor agonist cardiovascular outcome trials reported an HR of 0.89 (95% CI, 0.82-0.94) for a composite kidney outcome of development of severely elevated albuminuria, doubling of serum creatinine level, 40% or more decrease in eGFR, kidney replacement therapy, or death due to kidney disease.³⁴ Most of the GLP-1 receptor agonist trials showing kidney benefit included participants with substantially higher baseline prevalence of DKD than that in GRADE with beneficial effects of semaglutide demonstrated to be greater in patients with DKD at baseline.³⁵ These observations raise the possibility that GLP-1 receptor agonists are more effective at slowing the progression of established DKD than at preventing the development of DKD. Kidney outcome trials with GLP-1 receptor agonists in established DKD are ongoing.^{36,37} Meta-analyses of DPP-4 inhibitor trials, which similarly included cardiovascular trials with higher risk populations, have also noted a reduction in albuminuria; this has been attributed to an antiinflammatory and antifibrotic mechanisms.³⁸⁻⁴⁰

Limitations

These findings must be interpreted in the context of several limitations. Although GRADE followed up participants with T2D longer than any noncardiovascular outcome study in the current era, 5 years of follow-up remains brief for a low-risk population given that complications of diabetes, including DKD, develop over decades. Consequently, the number of events for the most serious and severe kidney outcomes, such as 40% decrease in eGFR, was low. Slightly greater weight loss in the liraglutide and sitagliptin groups leading to overestimation of UACR due to decreased creatinine excretion rate and lower use of RAAS inhibitors in the liraglutide group could have biased albuminuria results toward the null. A limitation of GRADE overall is the lack of an SGLT2 inhibitor arm owing to the fact that SGLT2 inhibitors were not approved at the time that GRADE was designed and launched; SGLT2 inhibitor treatment reduces eGFR slope decrease and albuminuria progression compared with placebo in lower risk subgroups similar to the GRADE cohort.¹³ We examined whether the addition of SGLT2 inhibitors influenced outcomes and did not find any effect; however, only 4.9% of participants used SGLT2 inhibitors, with most starting them relatively late in the trial, limiting power to evaluate this outcome. Although there were no observable differences in kidney outcomes across the 4 treatment groups, results from GRADE showing differential effects on total cardiovascular events, weight, and other outcomes may influence the selection of one medication over another.

Conclusions

As a randomized clinical trial of next-step therapy after metformin, GRADE enrolled a low-risk cohort of participants with T2D, largely free of cardiac and kidney disease at baseline. The results of GRADE suggest that, in people with T2D predominantly without kidney complications at baseline, a DPP-4 inhibitor, sulfonylurea, GLP-1 receptor agonist, or basal insulin added to metformin are equivalent with respect to the development or progression of DKD over 5 years.

ARTICLE INFORMATION

Accepted for Publication: March 19, 2023.

Published Online: May 22, 2023. doi:10.1001/jamainternmed.2023.1487

Author Affiliations: Massachusetts General Hospital Diabetes Center and Harvard Medical School, Boston, Massachusetts (Wexler); Kidney Research Institute, University of Washington, Seattle (de Boer); George Washington University Biostatistics Center, Rockville, Maryland (Ghosh, Younes, Bebu); Section of Endocrinology and Metabolism, Yale School of Medicine, New Haven, Connecticut (Inzucchi); Division of Endocrinology, Metabolism and Lipid Research, Washington University School of Medicine, St Louis, Missouri (McGill); VA San Diego Healthcare System and Division of Endocrinology and Metabolism, University of California San Diego School of Medicine, San Diego (Mudaliar): Division of Endocrinology, University of New Mexico Health Sciences Center, Albuquerque (Schade); Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis (Steffes); Division of Pediatric Endocrinology, Yale School of Medicine, New Haven, Connecticut (Tamborlane); Division of Metabolism, Endocrinology & Diabetes, University of Michigan, Ann Arbor (Tan); Division of Clinical and Molecular Endocrinology, Case Western Reserve University and Cleveland VA Medical Center, Cleveland, Ohio (Ismail-Beigi).

Author Contributions: Drs Ghosh and Younes had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. *Concept and design:* Wexler, Ghosh, Tan,

Ismail-Beigi. Acquisition, analysis, or interpretation of data: All

authors.

Drafting of the manuscript: Wexler, Ghosh, Schade. Critical revision of the manuscript for important intellectual content: All authors.

Statistical analysis: Ghosh, Younes, Bebu,

Tamborlane.

Obtained funding: Wexler.

Administrative, technical, or material support: Wexler, Schade, Steffes. Supervision: Tan.

Conflict of Interest Disclosures: Dr Wexler reported serving as a paid member of the Novo Nordisk data monitoring committee outside the submitted work. Dr de Boer reported receiving consulting fees from AstraZeneca, Bayer, Boehringer Ingelheim, George Clinical, Gilead, Goldfinch Bio, Cyclerion Therapeutics, Lilly, Medscape, and Otsuka, and nonfinancial support from DexCom for equipment and supplies for research outside the submitted work. Dr Inzucchi reported receiving personal fees from Boehringer Ingelheim, AstraZeneca, Novo Nordisk, Merck, Pfizer, Lexicon, VTV Therapeutics, Abbott, and Baver outside the submitted work. Dr McGill reported receiving grants from JDRF and Novo Nordisk; personal fees from Bayer, Boehringer Ingelheim, Lilly, Mannkind, Novo Nordisk, Provention Bio, Janssen, and Thermo Fisher; serving as a paid member of the National Institutes of Health (NIH) data safety and monitoring board (DSMB); personal fees from Jaeb Center for serving on the DSMB; and grants from Medtronic outside the submitted work. Dr Mudaliar reported receiving speaker's fees from AstraZeneca, consulting fees from Bayer, and grants from the NIH outside the submitted work. Dr Tan reported receiving a pension from Eli Lilly and Company outside the submitted work. No other disclosures were reported.

Funding/Support: The GRADE Study was supported by a grant from the NIDDK of the NIH under award number U01DK098246. The planning of GRADE was supported by a U34 planning grant from the NIDDK (U34-DK-088043). The American Diabetes Association supported the initial planning meeting for the U34 proposal. The National Heart. Lung, and Blood Institute and the Centers for Disease Control and Prevention also provided funding support. The Department of Veterans Affairs provided resources and facilities. The following organizations and grant numbers support clinical sites operations, but do not directly support the GRADE Study. The Department of Veterans Affairs provided resources and facilities. Additional support was provided by grants P30 DK017047, P30 DK020541, P30 DK020572, P30 DK072476, P30 DK079626, P30 DK092926, U54 GM104940, UL1 TROO0170, UL1 TROO0439, UL1 TROO0445, UL1 TROO1102, UL1 TROO1108, UL1 TROO1409, 2UL1TRO01425, UL1 TRO01449, UL1 TR002243, UL1 TRO02345, UL1 TRO02378, UL1 TRO02489, UL1 TR002529, UL1 TR002535, UL1 TR002537, UL1 TRO02541 and UL1 TRO02548. Educational materials have been provided by the National Diabetes Education Program. Material support in the form of donated medications and supplies has been provided by Becton, Dickinson and Company, Bristol-Myers Squibb, Merck & Co Inc, Novo Nordisk, Roche Diagnostics, and Sanofi.

Role of the Funder/Sponsor: GRADE was a parallel-group comparative effectiveness clinical trial with funding provided by the National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health. Institute collaborators were partners in the design, conduct, analysis, and publication of the study. Medications used in the trial were donated by pharmaceutical companies who had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Group Information: Members of the GRADE Research Group are listed in Supplement 3.

Disclaimer: The content of this article is solely the responsibility of the authors and does not necessarily represent the official views of the NIH.

Data Sharing Statement: See Supplement 4.

Additional Contributions: The GRADE Study Research Group is deeply grateful to the participants whose loyal dedication made GRADE possible.
